This exam has 10 questions, for a total of 100 points.

1. 8 points For each of the nodes 35, 52, 63, and 81, list the successor and predecessors of the node (if they exist).

Solution: (2 points each)
- For 35, 52 is the successor and 26 is the predecessor.
- For 52, 63 is the successor and 35 is the predecessor.
- For 63, 70 is the successor and 52 is the predecessor.
- For 81, there is no successor and 70 is the predecessor.

2. 10 points Draw the result of deleting the node with key 52, followed by deleting the node with key 63, from the below Binary Search Tree.

Solution: The node with key 52 has only one child, so we can attach its child to its parent. (5 points)

The node with key 63 has two children, so we can replace with with either its predecessor 25 or its successor 60. (5 points) Both solutions are shown below.
3. **10 points** Implement the `post_order` methods of the `Tree` and `Node` classes. They should return a list of the keys in the tree, ordered by the “post-order” traversal. For example:

```python
x = Node(8,
    Node(3, Node(1), Node(6, Node(4), Node(7)) ),
    Node(10, None, Node(14, Node(13))))
T = Tree(x)
assert T.post_order() == [1, 4, 7, 6, 3, 13, 14, 10, 8]
```

**Solution:**

```python
class Tree:
    def __init__(self, r):
        self.root = r

    def post_order(self):
        return self.root.post_order()

class Node:
    def __init__(self, k, l=None, r=None):
        self.key = k
        self.left = l
        self.right = r

    def post_order(self):
```
4. **10 points** What is a best DNA sequence alignment for the sequences TAG and ATG? When computing the score, use +2 for a match, -2 for a mismatch, and -1 for the gap penalty. Show your work by filling in the below dynamic programming table.

<table>
<thead>
<tr>
<th></th>
<th>T</th>
<th>A</th>
<th>G</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>T</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>G</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Solution:** One of several solutions is

```
TA_G
_ATG
```

(2 points for correct initialization of the table. 5 points for the rest of the table. 3 points for correct result from traceback.)

5. **12 points** Suppose that L is a Python `list` (array) of length n. Categorize the worst-case execution time of the below expressions as either

1. constant time (takes the same amount of time no matter what n is).
2. logarithmic time (takes time proportional to \( \log n \)).
3. linear time (takes time proportional to n)
4. quadratic (takes time proportional to \( n^2 \))

Label each operation with the above item number.
6. [6 points] What is the big-O worst-case time complexity of the following function, which raises \( x \) to the power \( n \), in terms of the input \( n \)? Assume that all the primitive number operations (multiplication, division, etc.) are constant time. Explain why your answer is correct.

```python
def exponent(x, n):
    if n == 0:
        return 1
    elif n == 1:
        return x
    elif n % 2 == 0:
        return exponent(x * x, n / 2)
    else:
        return x * exponent(x, n - 1)
```

**Solution:** In the worst-case, each time we divide in half we get an odd number, and have to make an extra call to \( \text{exponent} \). So we have \( 2 \lg n \) calls, but the factor of 2 is ignored for the big-O, so the time complexity is \( O(\lg n) \).

7. [10 points] Give the definition of \( \Theta \). Prove that if \( f(n) \in \Theta(g(n)) \) then \( g(n) \in \Theta(f(n)) \).

**Solution:** The definition of \( \Theta \) is: (2 points)

\[
\Theta(g(n)) = \{f(n) \mid \exists n_0. \forall n \geq n_0. \exists c_1, c_2. 0 \leq c_1 g(n) \leq f(n) \leq c_2 g(n)\}
\]
So we can assume
\[
\forall n \geq n_0. \ 0 \leq c_1 g(n) \leq f(n) \leq c_2 g(n)
\]
and we need to show that
\[
\forall n \geq n'_0. \ 0 \leq c'_1 f(n) \leq g(n) \leq c'_2 f(n)
\]
for some suitable choice for \(n'_0, c'_1, c'_2\). From \(f(n) \leq c_2 g(n)\) we have
\[
\forall n \geq n_0. \ \frac{1}{c_2} f(n) \leq g(n) \quad (2 \text{ points})
\]
and from \(c_1 g(n) \leq f(n)\) we have
\[
\forall n \geq n_0. \ g(n) \leq \frac{1}{c_2} f(n) \quad (2 \text{ points})
\]
Also, from \(0 \leq f(n)\) we have
\[
\forall n \geq n_0. \ 0 \leq \frac{1}{c_2} f(n) \quad (1 \text{ point})
\]
Putting these together we have
\[
\forall n \geq n_0. \ 0 \leq \frac{1}{c_2} f(n) \leq g(n) \leq \frac{1}{c_1} f(n)
\]
So we choose \(n'_0 = n_0\) (1 point), \(c'_1 = \frac{1}{c_2}\) (1 point), and \(c'_2 = \frac{1}{c_1}\) (1 point).

8. **9 points** What is the output of the following Python program?

```python
import math
def abs(n):
    return n

class Point1D:
    def __init__(self, x):
        self.x = x
    def distance(self, other):
        return abs(self.x - other.x)
    def abs(self, n):
        return n if n >= 0 else -n
    def transform(L, f):
        return [f(x) for x in L]

p1 = Point1D(3)
p2 = Point1D(5)
print(p1.distance(p2))
L = [Point1D(3), Point1D(5)]
```

```python
print(p1.transform(L, math.sin))
```
9. **10 points** Define a function in Python named `swap_range` with four parameters. The function should swap the elements of two sub-ranges within an array given by parameter \( A \). The beginning of the first subrange is given by parameter \( \text{begin1} \) and the beginning of the second subrange is given by parameter \( \text{begin2} \). The two sub-ranges have the same length, given by parameter \( n \). You may assume that \( \text{begin1} + n \leq \text{begin2} \).

Example use of `swap_range`:

\[
A = [1, 2, 3, 4] \\
\text{swap_range}(A, 0, 2, 2) \\
\text{assert } A == [3, 4, 1, 2]
\]

**Solution:**

```python
def swap(A, i, j):
    tmp = A[i]
    A[j] = tmp

def swap_range(A, begin1, begin2, n):
    for i in range(0, n):
        swap(A, begin1 + i, begin2 + i)
```

4 points for correct logic for swapping
4 points for looping over the array correctly
2 points for swapping the right elements

10. **15 points** The following code defines a linked-list data structure comprised of a `List` and `Node` class. Fill in the blanks of the implementation so that the unit test passes.

```python
class Node:
    def __init__(self, d, n = None):
        self.data = d
        self.next = n
class List:
    def __init__(self, array = []):
        self.head = ___(a)___
```

```python
def transform(L, lambda p: p.x * p.x))
D = {3: 'x', 'x': 3}
print(D['x'], D[3])

Solution: (3 points each)
-2
[9, 25]
(3, 'x')
for x in reversed(array):
    self.head = Node(x, self.head)

def equal(self, other):
    n1 = self.head
    n2 = ____(b)___
    while n1 and n2:
        if ___(c)___ != n2.data:
            return False
        n1 = ___(d)___
        n2 = n2.next
    return ___(e)___

if __name__ == "__main__":
    L = List([1,2,3])
    assert L.equal(L)
    L2 = List([4,5,6])
    assert not L.equal(L2)

Solution: (3 points each)
(a) None
(b) other.head
(c) n1.data
(d) n1.next
(e) True
